Atopy in Kashmir-validation from a case control study with respect to IgE and Interleukin genes

Taha Ashraf Qurashi¹, Aaliya Shah^{2†}, Gulzar Ahmad Bhat^{1†}, Mosin Saleem Khan^{1†}, Roohi Rasool³ and Syed Mudassar^{1*}

Abstract

Objectives: Increased levels of serum Immunoglobulin-E (IgE) and different genetic variants of cytokines are common biochemical manifestation in Allergy. The current study was aimed to study the association of IgE and different variants of Interleukin-4 (*IL-4*), and Interleukin-13 (*IL-13*) genes with different kind of allergies.

Methods: A pre-tested questionnaire was used to collect all the dietary, life style and clinical details by a trained staff. A blood sample of 2 ml each was collected in coagulated and anti-coagulated vials. DNA and serum samples were extracted and stored until further use. Serum IgE were estimated by ELISA while as the genotypic analysis was done by PCR-RFLP methods.

Results: Statistically a significant difference of serum IgE levels were observed among cases and controls ($P < 0.05$). The observed significant difference of serum IgE levels were retained among subjects who also harboured variant genotypes of *IL-4* and *IL-13* genes ($P < 0.05$). Additionally, the above genetic variants significantly modified the risk of allergy when stratification was done based on various clinical characteristics.

Conclusion: Our study suggests that increased IgE levels and in association with variant forms of *IL-4* and *IL-13* genes are significantly associated with different types of allergies in study population.

Keywords: IgE, Interleukin gene variants, Atopy, Case control study, Kashmir

Introduction

Allergic disorders are considered an epidemic in the developed world with rising incidence rate in the developing countries as well [1–3]. These disorders though multi-etiological but none has been established as a causative factor individually until now. The increased prevalence associated with large differences between urban and rural regions, hints at environmental factors

but genetics play a key role independently as well as in combination by modifying environmental and life style exposures.

The condition that result due to exposure of body to environmental substances is characterized by raised serum Immunoglobulin-E (IgE) levels- a feature of allergic diseases. It results due to immune reaction to an antigen called an allergen, which is normally harmless [4, 5]. Allergen-specific IgE- antibodies cause most allergic reactions. A number of atopy susceptibility interleukin genes have been identified which regulate the production of IgE [6, 7]. Genome wide Association studies have identified strong linkage of a region on chromosome 5q31–33 with atopic disorders in different

Full list of author information is available at the end of the article

populations [8–11]. Different interleukins (IL) like *IL-4* and *IL-13* genes been reported to regulate IgE synthesis and hence potentially involved in manifestation of allergic disorders [12–14]. The genetic polymorphisms in *IL-4* and *IL-13* genes are the most common genetic alteration in patients having atopic disorders. A number of studies regarding the different polymorphic variants of inflammatory genes and different allergic phenotypes are available [12, 14, 15]. Discovery of these genetic alterations has created the opportunity to develop novel clinical strategies for the management and treatment of these patients.

A number of studies regarding the different polymorphic variants of inflammatory markers and allergic phenotypes are available [12, 14, 15]. The hyperactive immune response in the form of increased levels of IgE and altered IL genetic variants as a common biochemical manifestation among allergic patients has been reported previously [16–20]. Considering, the above findings and possibility of higher incidences of allergies due to suitable environmental settings for allergies in the form of fluffy seeds from poplar trees and blooms in Kashmir, we intend to identify the patients having different types of allergic disorders, elucidate their serum IgE levels, and find out any possible correlation with certain gene variants of *IL-4* and *IL-13*.

Materials and methods

Patients and controls

A total of 528 subjects presented with different allergic symptoms attending Allergy Clinic, Sher-i-Kashmir Institute of Medical Sciences (SKIMS), Department of Dermatology, SKIMS Medical College and Department of Dermatology, Sheri Maharaja Hari Sing (SMHS) Hospital Srinagar were included in this study. A subject is diagnosed as “Atopic” if they have presence of any/all of the phenotypes like; allergic rhinitis (AR), atopic dermatitis (AD), and bronchial asthma (BA) called as allergic triad. Persons with Atopy also have a tendency to have allergic conjunctivitis, food allergy and occupational allergy apart from the above phenotypes. Blood samples were collected from all 528 cases. Blood samples were also obtained from 610 no-atopic subjects from the Out Patients Departments of above Departments. A written pre-informed consent was obtained from all cases and controls. The study was approved by the Institutional Ethical Clearance Committee of SKIMS, Srinagar vide order No. SIMS 1 131/IEC-SKIMS/2016–133.

Case control selection and data collection

The subject selection was based on the following.

Inclusion criteria

All individuals with AD, AR, and BA were included in the study as cases. Patients with allergic conjunctivitis, food allergy, and occupational allergy were also included in the study as cases, in addition to AD, AR, and BA. Those who did not have any of the aforementioned allergic problems served as control subjects.

Exclusion criteria

Individuals with any genetic disorder, malignancy, chronic obstructive pulmonary disease and acute chronic obstructive pulmonary disease were excluded from the study. Individuals on beta-blockers and/or with any sort of autoimmune disorder are not eligible for immunotherapy, so they were also excluded from the study.

Data collection

Detailed information on age, sex, place of residence, ethnicity, religion, education, dietary data and other potential confounding factors of interest was collected using a questionnaire pre-designed for the study population. Detailed information on life-long history of use of several tobacco products was obtained. Information on family history of any allergic disorder was obtained from all the participants. To assess the socio-economic status (SES) of the subjects, information on potential parameters of SES was obtained including education level (highest level attained), monthly income (INR), house type and ownership of several household appliances. Similarly, the information regarding, second hand smoking was also acquired from all the recruited subjects.

Specimen

After obtaining verbal and written consent from all cases and controls, at least 4 ml of blood sample was collected from both cases and controls in EDTA and red top vials. Serum and whole blood sample containing vials were stored at – 20 °C until further use. Serum samples were used to measure the *IL-4* and *IL-13* levels by Enzyme linked Immunosorbent assay (ELISA). Whole blood samples were used for DNA extraction followed by polymorphic analysis of *IL-4*, *IL-13* and *STAT6* genes.

Skin prick test (SPT)

European Academy of Allergy and Clinical Immunology (EAACI) recommendations were used to perform SPT. Saline was used as negative control and histamine 10 mg/ml was used as positive control. Antihistamines

were discontinued before skin testing according to published guidelines. Skin tests were considered positive if at least one allergen elicited a wheal reaction of more than 3 mm of diameter after subtraction of the negative control. Patients were considered atopic if at least they had one positive skin test result.

Estimation of Biochemical and Hematological markers

Serum samples were used for estimation of IgE and Vitamin D levels on Access 2 Immunoassay System (Beckman Coulter, Inc., USA) using CLIA technique. Whole blood samples were used for estimation of eosinophil count on Sysmex XP-300™ Automated Hematology Analyzer (Sysmex America, Inc., USA) and Erythrocyte sedimentation rate (ESR) using Westergren method. IgE level of > 180 IU/ml was taken as “Elevated”. In case of Vitamin D levels, < 20 ng/ml was considered as “Deficient”, 20–30 ng/ml as “Insufficient”, 31–100 ng/ml as “Sufficient” and > 100 ng/ml as “Upper safety limit”. Relative eosinophil count > 6% of peripheral blood was considered as “Elevated”. ESR of > 15 mm/hr in males; > 20 mm/hr in females; > 10 mm/hr in children was taken as “Elevated”.

Pulmonary function test

A spirometry test was performed to assess the pulmonary function of each enrolled patient. Forced expiratory volume in 1ST second (FEV1) is a very good and direct indicator of lung function. FEV1 of less than 80% was considered as “Abnormal”. Post Broncho dilatory Response (PBD) is change in FEV1 after 15–20 min of use of Bronchodilator (Salbutamol; 200 µg). PBD of “> 200 ml and > 12%” is significant for a Reversible Lung disease like Asthma. If PBD is “< 200 ml and < 12%” the reversibility is not significant as we see in Chronic Pulmonary Obstructive Disease (COPD) and Asthma COPD Overlap Syndrome (ACOPD). Forced vital capacity (FVC) is an indicator of Restrictive lung disease hence not included in our analysis.

ELISA principle and method

The ELISA was done as described previously [21]. Briefly, a capture antibody highly specific for IL-4 and IL-13 were coated to the wells of the microtiter strip plate. Binding of IL-4 and IL-13 in samples and known standards to the capture antibodies was completed and any excess unbound analyte was removed. During the next incubation period the binding of the biotinylated anti-IL-4 and IL-13 secondary antibody to the analyte occurs. Any excess unbound secondary antibody was then removed. The HRP conjugate solution was then added to every well including the zero wells. Following incubation excess conjugate was removed by careful washing. A

chromogen substrate was added to the wells resulting in the progressive development of a blue coloured complex with the conjugate. The colour development was then stopped by the addition of acid turning the resultant final product yellow. The intensity of the produced coloured complex is directly proportional to the concentration of IL-4 and IL-13 present in the samples and standards. The absorbance of the colour complex was then measured and the generated OD values for each standard are plotted against expected concentration forming a standard curve. This standard curve can then be used to accurately determine the concentration of IL-4 and IL-13 in as many samples tested. The primary wavelengths for IL-4 and IL-13 measurement were 450 nm and 630 nm, respectively.

Sensitivity

The sensitivity or minimum detectable dose of IL-4/IL-13 using diaclone IL-4/IL-13 ELISA kit was found to be 0.3 pg/ml and 1.5 pg/ml respectively. This was determined by adding 3 standard deviations to the mean OD obtained when the zero standard was assayed 3–5 times. However, we had considered 0.7 pg/ml as the minimum value below which the interleukin levels were treated as undetectable in order to be in line with most of the currently used moderately sensitive ELISA kits.

Genetic analysis

Besides environmental and lifestyle factors, genetics factors also play an important role in the development of allergic disorders. Genetic variants of these interleukin genes have previously been associated with different allergic phenotypes [22] and a detailed account of different gene variants of *IL-4* and *IL-13* have been done as discussed elsewhere [23]. For identification of the studied genotypes, PCR-RFLP analysis was performed [24], the details of which are provided in Table 1.

Statistical analysis

Different categorical variables were set for calculating number and percentages for different genotypes of studied genes. Test for Hardy–Weinberg Equilibrium (HWE) were conducted by comparing observed and expected genotype distributions by the χ^2 goodness of fit. Statistical significance for departure of a genotype frequency from its expected frequency under the HWE model was set at $P \leq 0.05$. Conditional logistic regression models were used to calculate odds ratios (ORs) and corresponding 95% confidence intervals (95% CIs) to assess the association of the genotypes with allergies. All statistical analysis was done using STATA software, version 14 (STATA Corp., College Station, TX, USA).

Table 1 Frequency distribution of selected demographic and risk factors in atopy cases and controls of the study

Characteristics	Cases (n = 528)	Controls (n = 610)	P value

Two sided *P* values < 0.05 were considered as statistically significant.

Results

Characteristics of study subjects

In this study 60.2% (n = 318) of the cases were females and 39.8% (n = 210) were males with a male:female ratio of 0.7:1. On the basis of age, the patients were grouped into two categories, less than 40 (< 40) and greater or equal to 40 (≥ 40) years of age. The number of cases in the age group of < 40 (n = 414; 78.4%) exceeded as compared

to ≥ 40 years (n = 114; 21.6%) with an overall mean age of 29.7 ± 13.9 years. Based on the smoking status, 63 (12%) patients were smokers who were inclusively males, 165 (31.2%) were non-smokers and 300 (56.8%) were passive smokers. There were 525 (99.4%) patient with elevated (≥ 180u/l) IgE levels while as only 3 (0.6%) patients had normal (< 180u/l) IgE levels. Other study variables of the study subjects with atopy are shown in Table 1.

Among controls, 58.2% (n = 355) of the subjects were females and 41.8% (n = 255) were males. The number of control subjects in the age group of < 40 (n = 459; 75.0%)

exceeded than ≥ 40 years ($n = 151$; 25.0%). The mean age of the control subjects was 29.45 ± 14.2 years. Based on the smoking status, 38 (6.2%) controls were smokers who were inclusively males, 345 (56.5%) were non-smokers and 227 (37.3%) were passive smokers. There were 123 (20.2%) controls with elevated IgE levels while as 487 (79.8%) had normal IgE levels. Other clinicopathological and clinico-epidemiological characteristics of controls are shown in Table 1.

There were no significant differences among cases and controls in terms of mean age, gender distribution and smoking, although, more non-smokers were present in controls than in cases (56.5% vs 31.2%). Similarly, substantially higher number of case (99.4%) showed increased serum IgE levels than controls (20.2%).

Serum cytokine levels (IL-4 & IL-13) in cases and controls

In the present study we analyzed the serum IL-4 and IL-13 levels in cases and controls in order to evaluate their association with the risk of Atopy in Kashmiri population.

Serum IL-4 levels and their association with demographic and clinicopathological characteristics of cases and controls

The frequency of detectable IL-4 levels was found to be higher for cases (408 out of 528 i.e. 77.3%) than controls (117 out of 610 i.e. 19.1%), a difference which is statistically significant ($P < 0.01$). The median IL-4 levels in cases and controls was found to be 2.57 (0.0–23.35) and 0.08 (0.0–4.37) respectively (Table 2).

On further stratification, association between IL-4 levels and clinico-pathological variables was analyzed between cases and controls. It was observed that there was a statistically significant difference in the frequency of detectable and undetectable IL-4 levels between cases and controls with respect to all the subgroups of IgE levels, age, gender, dwelling, smoking status, eosinophil count and vitamin D levels ($P < 0.01$) (Table 3).

Frequency of detectable IL-4 levels was more common in cases with year round allergy as compared to patients with seasonal allergy (OR=0.5, $P = 0.01$), in cases with

other co-morbidities ($P = 0.02$) and patients with all the differential diagnosis of Atopy ($P = 0.03$) (Table 3).

When the different studied polymorphisms of *IL-4RA*, *IL-4*, *IL-13* and *STAT6* genes were compared with IL-4 levels of Atopy patients the statistical significance was noted with *IL-4RA* A148G (OR=2.0; $P = 0.01$), *IL-13* A1512C (OR=0.5; $P = 0.05$) and *STAT6* G2964A (OR=0.6; $P = 0.03$) respectively (Table 4).

Serum IL-13 levels and their association with demographic and clinicopathological characteristics of cases and controls

Detectable IL-13 levels in Atopy patients and matched controls were analysed in order to evaluate its association with the risk of Atopy in Kashmiri population. All cases had *detectable* IL-13 levels (528 of 528; 100.0%) as compared to controls (395 of 610; 64.7%), a difference which is statistically significant ($P < 0.01$). The median IL-13 levels in cases and controls were found to be 13.79 (5.98–42.47) and 2.32 (0.0–6.51) respectively (Table 2). There was a significant difference between detectable and undetectable IL-13 levels of cases and controls ($P < 0.0001$).

On comparing IL-13 with various clinicopathological variables, a statistically significant difference in the frequency of detectable and undetectable IL-13 levels were observed in both the groups with respect to all the subgroups of IgE, age, gender, dwelling, smoking status, levels, eosinophil count and vitamin D levels so consequently there was no overall statistical significance with respect to these clinicopathological characteristics ($P < 0.0001$). However, association between IL-13 levels and demographic/clinicopathological characteristics did not presented any significant association among cases ($P > 0.05$) (Table 5).

When the different studied polymorphisms of *IL-4RA*, *IL-4*, *IL-13* and *STAT6* genes were compared with IL-13 levels of Atopy patients the statistical significance was not noted with any of the polymorphisms (Table 6).

Correlation analysis of various parameters between cases and controls is presented in Figs. 1, 2, 3 and 4. Most of the studied parameters showed a positive but significant correlation between cases and controls.

Table 2 The number of subjects with detectable serum *IL-4* and *IL-13* levels along with its median and range in patient and control group

Cytokines (pg/mL)	Cases		Controls		P value
	N (%)	Median (min–max)	n (%)	Median (min–max)

Discussion

IgE plays an important role in the development of allergic disorders. Current evidence shows that high-affinity IgE in blood stream of allergic individuals derives mainly from the mucous membrane. The production of IgE requires the activation of the adaptive immune system. B cells in the secondary lymphoid organs are stimulated to produce mature antibodies [25]. Moreover, the stimulus upon exposure of allergens in the mucosa might produce a sequential switching to IgE from IgG or IgA [26, 27]. A study from early 1990s demonstrated that house dust

mite-specific IgE increased faster in the nasal secretions than in serum after allergen exposure [28]. Similarly allergic rhinites patients on exposure to pollen showed significant changes in IgE repertoires in nasal mucosa [29, 30].

Different cytokines are modulating factors of the immune response and inflammatory reactions and are involved in the pathogenesis of allergies. In this study, we observed a substantial increase in serum IgE levels among atopic subjects as compared to non-atopic controls ($P < 0.05$). In subjects with increased levels of

IL Interleukin, *U* undetectable, *D* detectable

0.7 pg/ml is the minimum value below which the interleukin levels (*IL-4*) were treated as undetectable

1.5 pg/ml is the minimum value below which the interleukin levels (*IL-13*) were treated as undetectable

serum IgE levels, we observed higher percentage of variant genotypes of *IL-4* and *IL-13* genes. Additionally, there was an increased serum *IL-4* and *IL-13* levels among atopic patients as compared to controls.

Our results are completely in agreement with earlier epidemiological studies which reported higher IgE levels associated with bronchial responsiveness, a major component of the asthma phenotype, rhinitis and dermatitis [31–33]. In recent years, a high serum levels of IgE is used to predict the development of asthma, independent of other allergic factors. Therefore, an understanding of the genetic mechanisms regulating total serum IgE levels will be effective to scrutinize the hereditary components of different atopic disorders, complex genetic disorders influenced by the interactions among multiple genes and environmental exposures [34]. In another study, a two-locus segregation analysis revealed evidence of two major gene locus on chromosome 5 (5q31-533) and a residual genetic effect regulating total serum IgE levels in asthma patients [35]. Several studies have found evidence for a recessive gene regulating IgE levels, with different estimates of gene frequencies and mean IgE levels [36].

IL-13 and *IL-4* genes have been reported to play an important role in allergy [37, 38]. They recruit eosinophils and mast cells, induce B-cells for IgE synthesis [39]. In addition, *IL-4* is also responsible for regulating differentiation of naive T cells into Th2 subtype. In response to allergen *IL-4* strongly influence bronchial hyperactivity resulting in airway inflammation, mucus hypersecretion and airway remodelling [20]. Previous studies have shown that SNPs in the *IL-4* promoter may influence the response of mast cells to IgE-mediated signaling [16]. Polymorphism rs2243250 was associated with IgE levels, asthma, rhinitis and dermatitis [40, 41]. The studied polymorphism of *IL-4* has also been associated with different atopic disorders like atopic asthma and increased total IgE level [42]. In *IL-13* gene, a functional SNP contributing to amino acid substitution R110Q (rs20541) was described to change the binding strength of *IL-13* to its receptor, causing higher activity of Gln110 variant [17]. Numerous studies showed that this polymorphism correlated significantly with higher total IgE levels among allergic patients [38, 43]. Furthermore, study by Choi et al. describes significant association with an increase in total serum IgE levels in

1.5 pg/ml is the minimum value below which the interleukin levels (IL-13) were treated as undetectable

children with atopic asthma in Korean population for rs20541 and rs1805010 polymorphisms [44], which is completely in agreement with our results. In allergic subjects, Th2 phenotype predominates, leading to increased production of serum IL-13 and class-switching in B lymphocytes to synthesize IgE antibodies [45, 46].

Arima et al. have found, using animal model, that *IL-13* with Gln110 variant has higher activity and is present in blood for a longer time [17]. This was confirmed by Chen et al. [47, 48], who performed the experiments on mouse cell line with stable expression of human *IL-13R*, that had the ability to bind human *IL-13* gene. In agreement with

IL Interleukin, *U* undetectable, *D* detectable

0.7 pg/ml is the minimum value below which the interleukin levels (*IL-4*) were treated as undetectable

1.5 pg/ml is the minimum value below which the interleukin levels (*IL-13*) were treated as undetectable

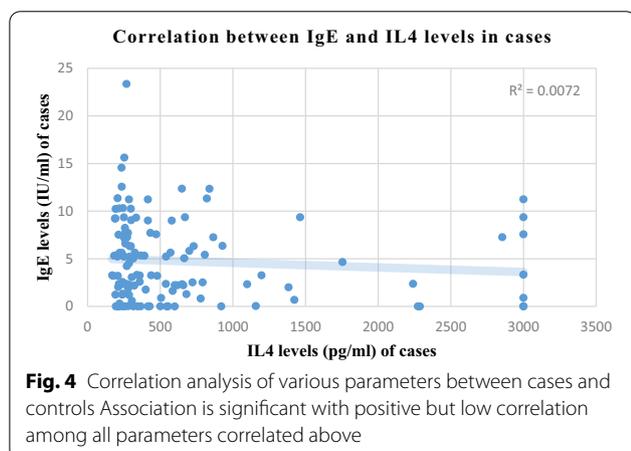

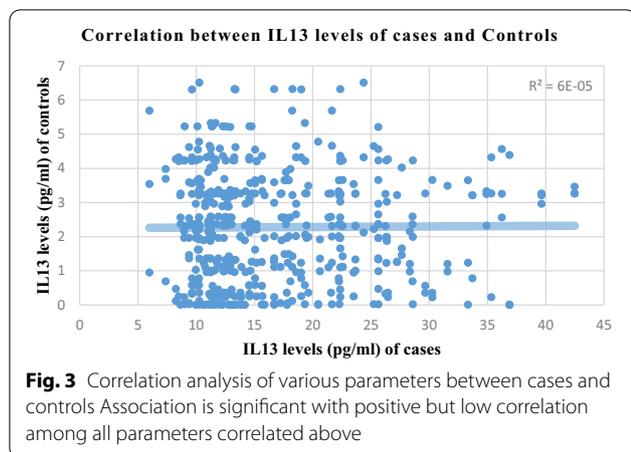

the above findings, we observed a significant increase in IgE levels among subjects harboring the variant forms of studied genes.

Conclusion

The current findings suggest that IgE and interleukin genes play a key role in allergy disease development. Significantly raised serum levels of IgE, as well as both

of the study’s inflammatory markers were observed among cases as compared to controls. With respect to several subgroups including serum IgE levels, age, gender, residence, smoking status, eosinophil count, and vitamin D levels, there was a significant difference in the frequency of detectable and undetectable *IL-4* and *IL-13* levels between patients and controls. Only a few genotypes exhibited a significant difference between

detectable and undetectable IL-4 serum levels, while IL-13 levels revealed no significant difference.

The strength of the study is that no study has reported the exposure of these genotypes with atopic disorders alone or in combination with these environmental exposures in Kashmiri population. Other major strength is comparatively larger sample size and confounding of the results with the probable allergy risk factors. However, selection or recall bias could be the weak point of this study, although the same hospital setting and only a single interviewer lessen this bias.

Acknowledgements

The authors gratefully acknowledge the volunteer participation of patients. The authors are also thankful to technical staff of the Department of Clinical Biochemistry and Department of Immunology, Molecular Medicine for their support.

Authors' contributions

TAQ—Concept, design of study, data collection and article draft; AS, GAB, MSK—Data collection, data analysis, interpretation and manuscript review RR -Provided Patient samples and SM—Concept and study design. All authors read and approved the final manuscript.

Funding

Not funding was received for the said study. The authors utilized their own expenses.

Availability of data and materials

Not applicable.

Declarations

Ethics approval and consent for participate

A written consent was taken from all the patients prior to their recruitment; they were also apprised about the ongoing study, which was approved by Institutional Ethical Clearance Committee of Sher-I-Kashmir Institute of Medical Sciences Srinagar, India vide order No. SIMS 1 131/IEC-SKIMS/2016–133. A written pre-informed consent was obtained from all cases and controls.

Consent to publication

All authors have approved the manuscript for submission and possible publication.

Competing interests

The authors declare that there is no conflict of interests in the form of financial and personal relationships with other people or organizations that could lead to any kind of bias.

Publisher's Note

Springer Nature remains neutral with regard to jurisdictional claims in published maps and institutional affiliations.

Ready to submit your research? Choose BMC and benefit from:

- fast, convenient online submission
- thorough peer review by experienced researchers in your field
- rapid publication on acceptance
- support for research data, including large and complex data types
- gold Open Access which fosters wider collaboration and increased citations
- maximum visibility for your research: over 100M website views per year

At BMC, research is always in progress.
